Benchmark datasets: HELOC

Parametric vs Nonparametric techniques

Non-parametric Models

Complexity of the model grows with the size of the training data

- K-Nearest Neighbors
- Decision Trees

Parametric Models

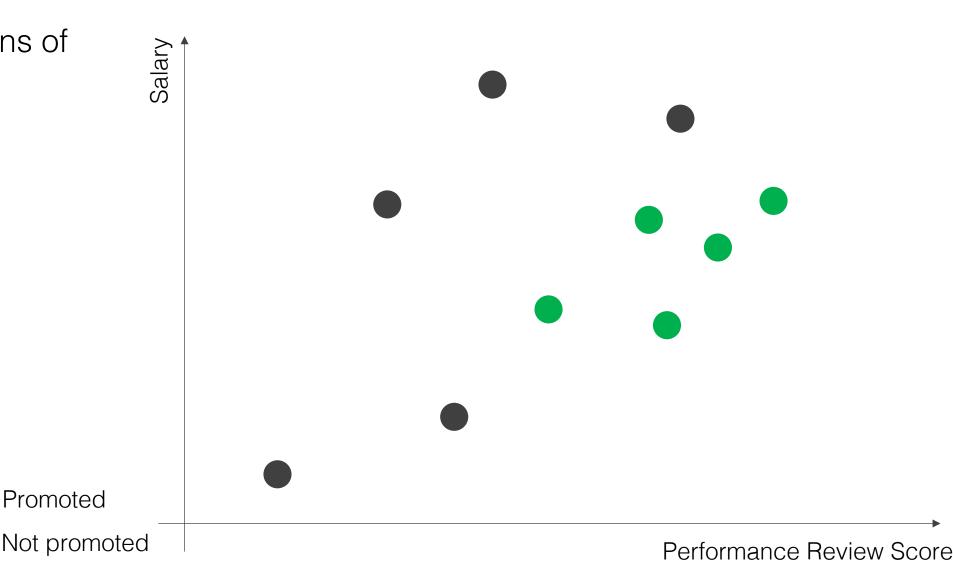

Fixed number of parameters (i.e. a fixed structure)

- Linear regression
- Logistic regression
- LDA, QDA
- Naïve Bayes with Gaussian likelihoods

Classification trees = decision trees

Promoted

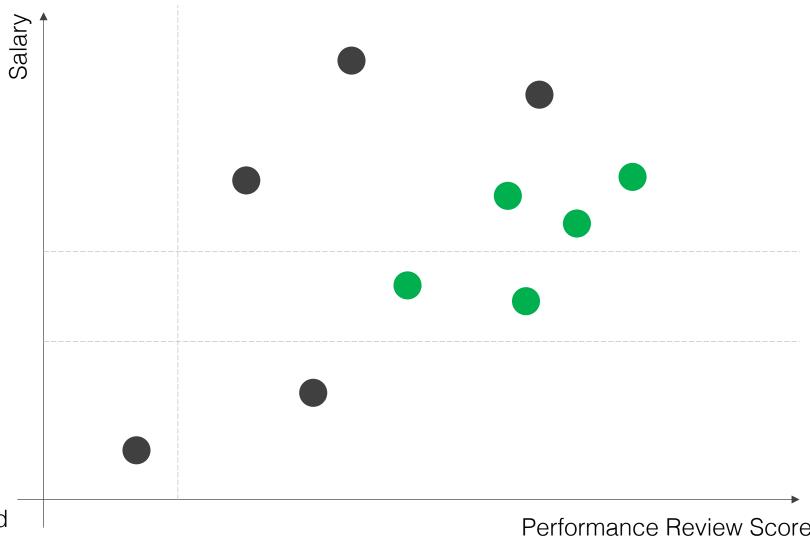

Predicting promotions of salaried employees

Kyle Bradbury

Predicting promotions of salaried employees

Find the best "split" in any one feature (that best classifies the data) that divides the region in two

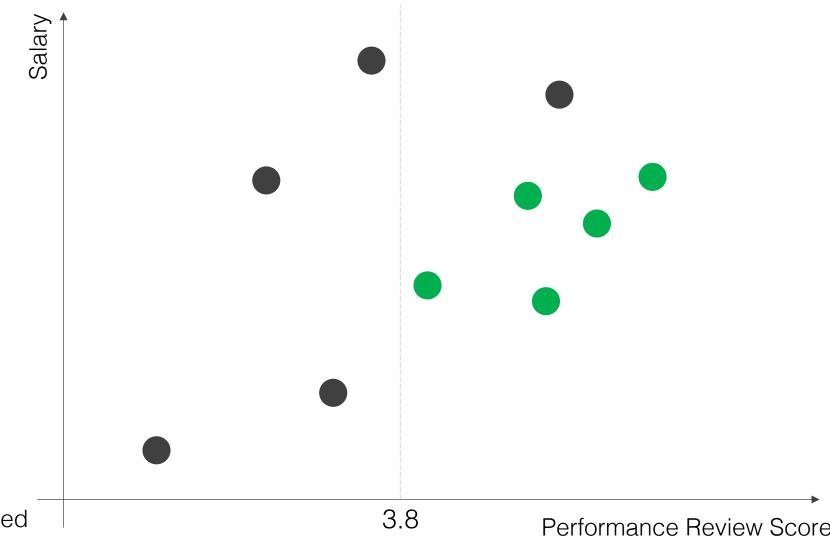

Promoted

Not promoted

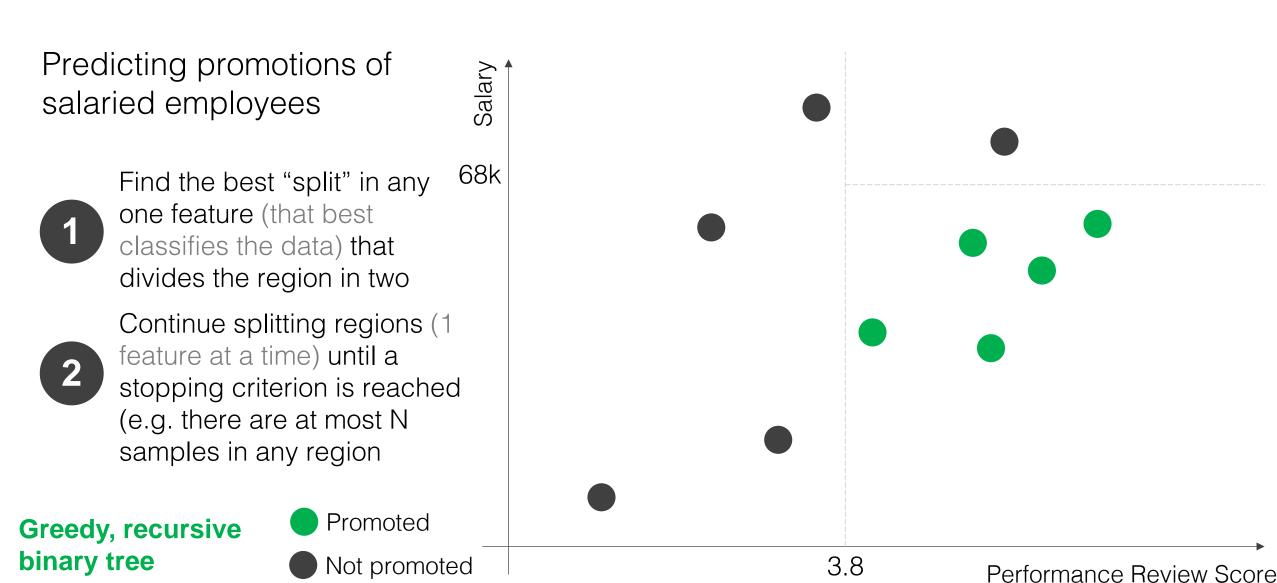

Predicting promotions of salaried employees

Find the best "split" in any one feature (that best classifies the data) that divides the region in two

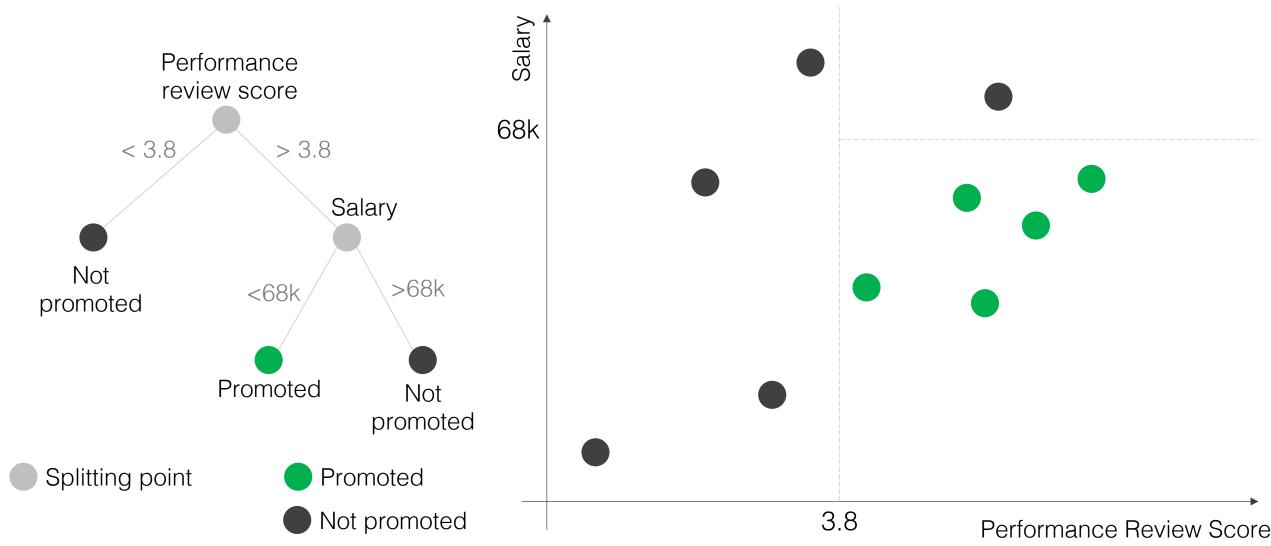

Promoted

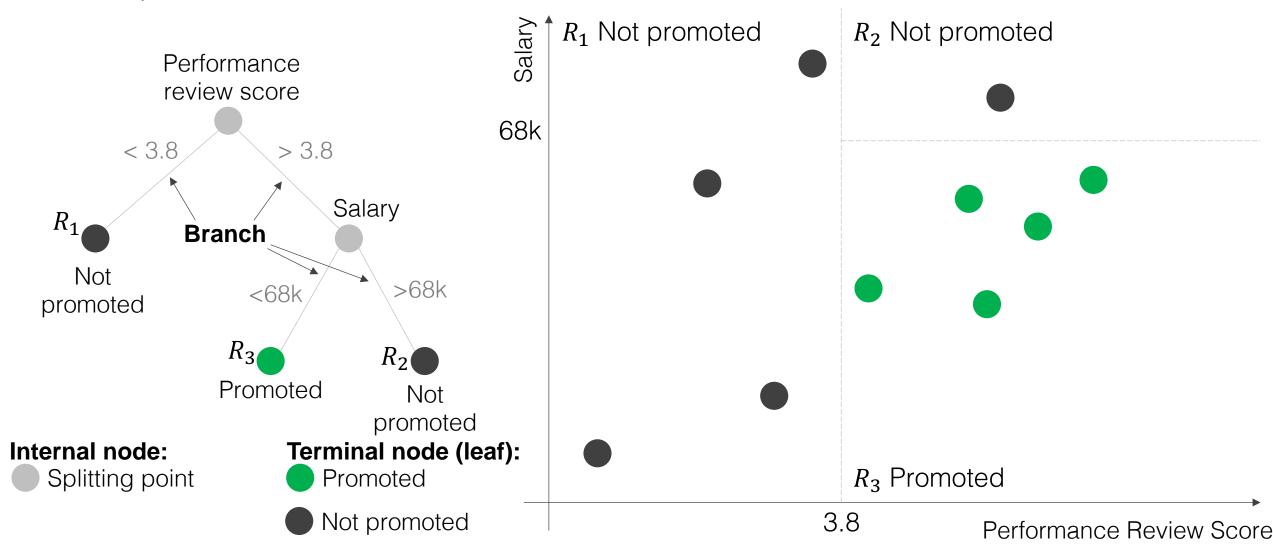

Not promoted

Tree representation:

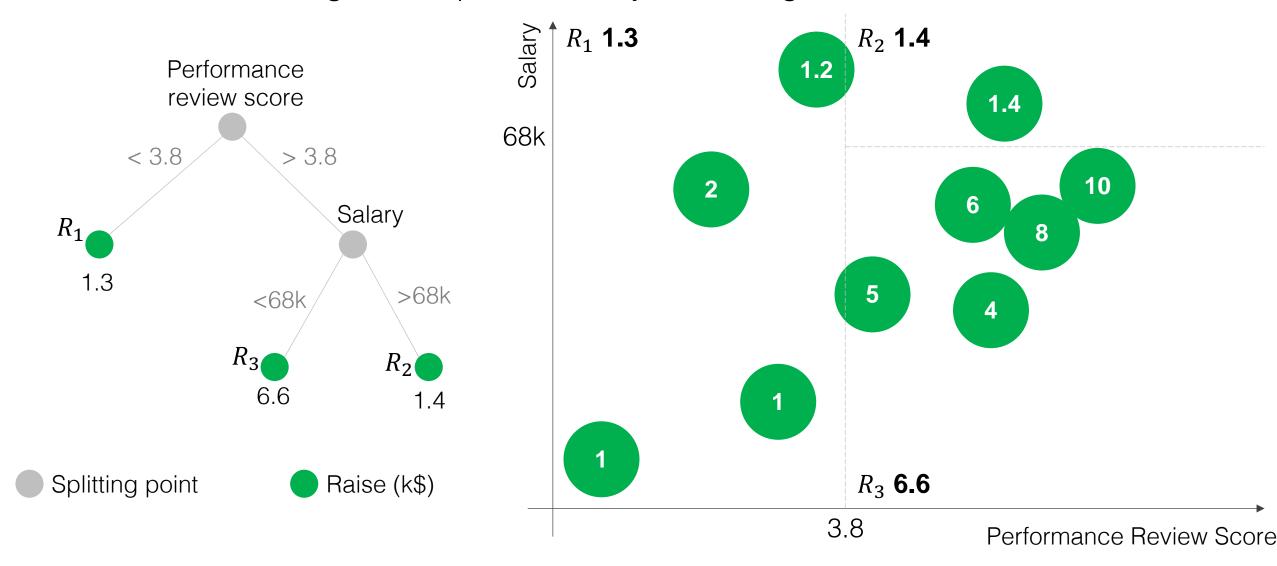

Tree representation:

The Regression Setting

In this case, each region is represented by an average of the values it contains

How do we determine which split to make?

Pick the split that reduces the error/cost criterion most after the split

Splitting criterion

$$C = \sum_{r=1}^{R_{tot}} Q(r)$$

Regression

Kyle Bradbury

Mean square error

$$Q_{MSE}(r) = \sum_{i \in R_r} (y_i - \hat{y}_{R_r})^2$$

 y_i = training data response i \hat{y}_{Rr} = mean value in region r, (where R_r is the set of samples in region r)

Classification

Misclassification rate

$$Q_{Misclass}(r) = 1 - \max_{k} \ (\hat{p}_{rk})$$

Gini impurity

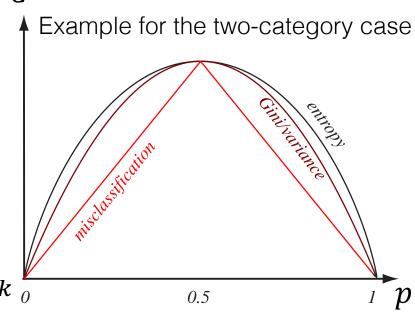

Measure of how often a randomly chosen element from the set would be incorrectly labeled if it was randomly labeled

$$Q_{Gini}(r) = \sum_{k=1}^{K} \hat{p}_{rk} (1 - \hat{p}_{rk})$$

Cross-entropy

$$Q_{entropy}(r) = -\sum_{k=1}^{K} \hat{p}_{rk} \log \hat{p}_{rk} \frac{1}{p_{rk}}$$

 \hat{p}_{rk} = proportion of training observations in the r^{th} region from the k^{th} class

Duda, Hart, and Stork., Pattern Classification

How to measure quality of split for classification?

Class 1

Class 2

r=2

 \hat{p}_{rk} = proportion of training observations in the r^{th} region from the k^{th} class

For each region:

Misclassification rate

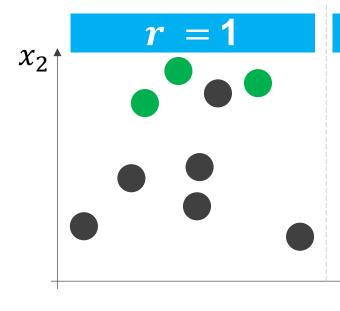

$$Q_{Misclass}(r) = 1 - \max_{k} (\hat{p}_{rk})$$

0.333

Gini impurity

$$Q_{Gini}(r) = \sum_{k=1}^{K} \hat{p}_{rk} (1 - \hat{p}_{rk})$$

 $\hat{p}_{11} = 3/9$

 $\hat{p}_{12} = 6/9$

 $\hat{p}_{21} = 5/6$

$$\hat{p}_{22} = 1/6$$

Cross-entropy

$$Q_{entropy}(r) = -\sum_{k=1}^{K} \hat{p}_{rk} \log \hat{p}_{rk} \quad _{0.637}$$

Tree Pruning

Trees have the tendency to overfit the data

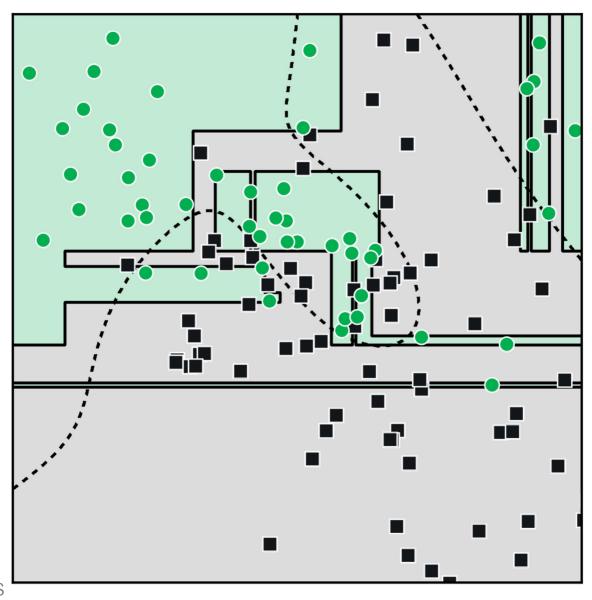

Consider the stopping rule: stop splitting once there is only 1 class of observations in each region (leads to complete overfit)

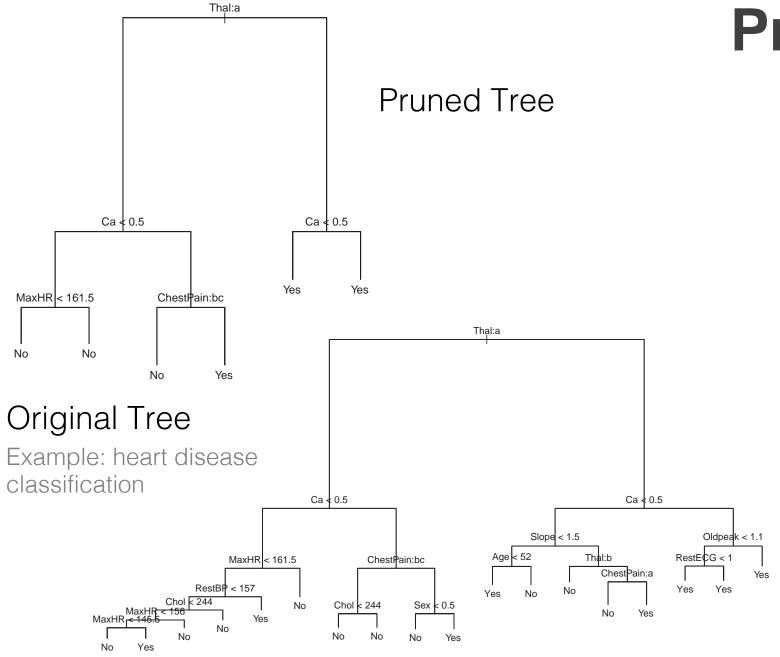

Pruning the tree reduces this overfit (removing splits after the tree is formed)

Pruning can be optimized through a penalty on the number of terminal nodes:

$$C_{Prune} = \sum_{j=1}^{T} \sum_{i \in R_j} \left(y_i - \hat{y}_{R_j} \right)^2 + \alpha T$$
penalty on number of terminal nodes

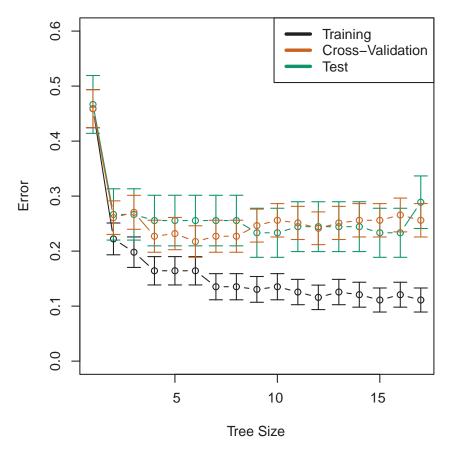

Decision Tree

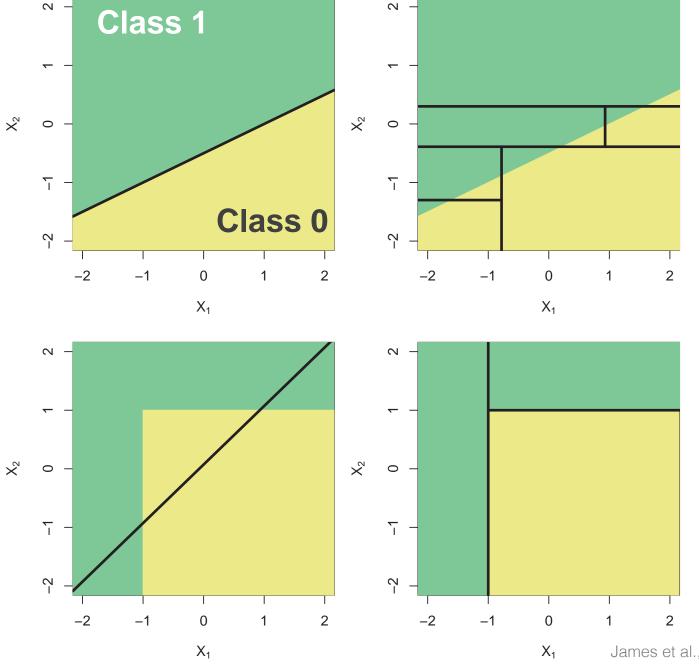

Pruning example

Performance

James et al., An Introduction to Statistical Learning

Linear model

Classification Tree

Struggle when the boundary is not parallel to an axis

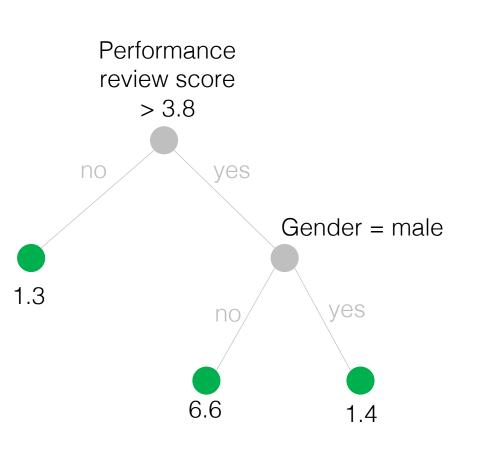

...nonlinear feature transforms could help...

James et al., An Introduction to Statistical Learning

Pros/Cons

Numerical data

Categorical data

Pros:

Trees easily handle multiple types of data

Trees are easy to interpret

Cons:

Trees do not typically have the same level of predictive accuracy of other methods

Tend to overfit (have high variance)

Ensemble learning

Combining models to improve performance beyond any individual model alone

Bagging (bootstrap aggregation)
Random forests (tree-specific modification of bagging)
Gradient boosting

Reducing Variance or Bias through ensembles

Bagging

Boosting

Models in ensemble:

high variance, low bias (i.e. overfit models)

high bias, low variance (i.e. underfit models, "weak learners")

Effect of aggregating:

Reduce variance through averaging output

Reduce bias through sequentially fitting models to previous model errors

Bootstrap aggregation

Trees overfit (have high variance). Averaging over observations reduces variance

Recall bootstrap sampling (sampling with replacement):

Original Data:

Bootstrapped sample 1:

Bootstrap aggregation

- 1 Create a random bootstrap sample from the training data
- Train a model on that bootstrap sample and call it $\hat{f}_b(x)$
- Repeat 1 and 2 until we have B models trained on different bootstrap samples
- Take the average of the output for our new model estimate:

$$\hat{f}_{bag}(\mathbf{x}) = \frac{1}{B} \sum_{b=1}^{B} \hat{f}_b(\mathbf{x})$$

(for classification models we can get the average class confidence or take a majority vote)

Tree Number:

First split:

Trees:

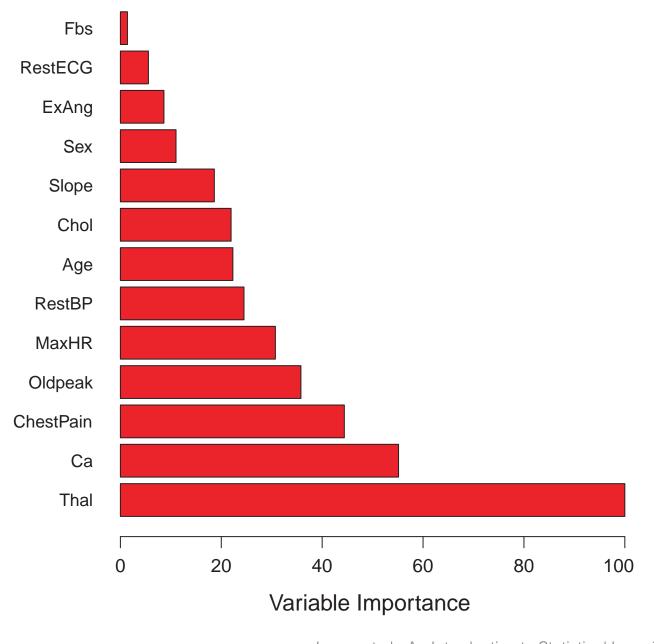

Variable Importance

Decision trees are very interpretable, but this is lost with bagging

We can construct another measure called "variable importance" to compare feature contributions

Calculate the total amount the error (or impurity) decreased by splitting on each feature.

Average over all the trees resulting from bagging

James et al., An Introduction to Statistical Learning

Kyle Bradbury

Tree-based Methods & Ensembles

Lecture 11

Random Forests

A small tweak on bagging

Random forests decorrelate the bagged trees

Decision trees are constructed greedily

This can lead to highly correlated trees

"Strong" features will typically be split before moderately strong predictors.

Each time a split is considered, a **random subset of** m **features** is selected as candidates from the full set of p features

Typically chose:
$$m = \sqrt{p}$$

(If m = p, then we would be back to the bagging approach)

Random forests

Observations Included: (out of 1-9)

[1,2,3,3,8]

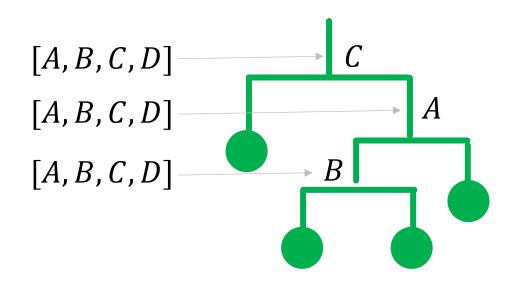

[1,2,3,3,8]

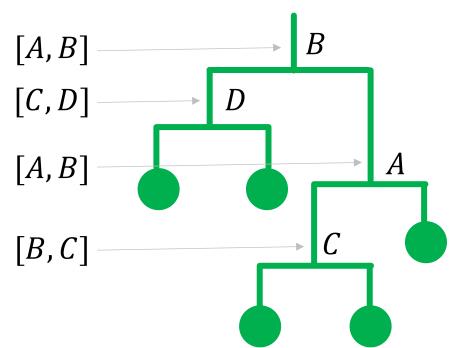

Features list:

[A, B, C, D]

[A, B, C, D]

Feature options for each split:

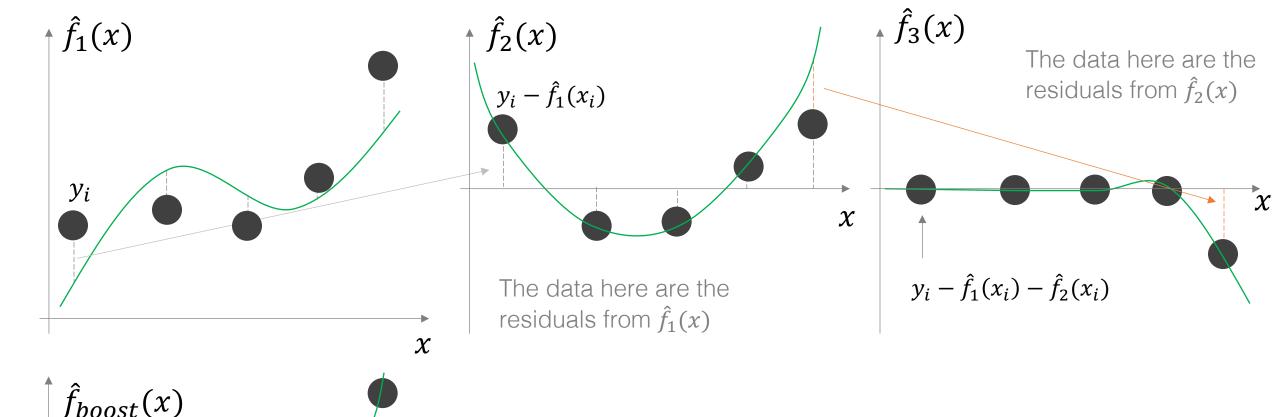

Boosting

Bagging created trees that were designed to be as independent as possible

Boosting involves building trees **sequentially**, each building on the errors of the last

We build consecutive models, each fit to the residuals of the last model

We sum models output to get the boosted prediction $\hat{f}_{boost}(x) = \hat{f}_1(x) + \hat{f}_2(x) + \hat{f}_3(x)$

Boosting

 y_i

Boosting for regression trees

- 1 Select the number of models to train, B, and learning rate λ
- λ slows down the learning process to avoid overfitting

- Set $\hat{f}(x) = 0$ and $r_i = y_i$ for all the training data
- Fit a tree, $\hat{f}_b(x)$ to the residuals, r_i (with d splits)
- 4 Update $\hat{f}(x) \leftarrow \hat{f}(x) + \lambda \hat{f}_b(x)$
- 5 Update the residuals $r_i \leftarrow r_i \lambda \hat{f}_b(x_i)$
- 6 Output the boosted model: $\hat{f}(x) = \sum_{b=1}^{\infty} \lambda \hat{f}_b(x)$

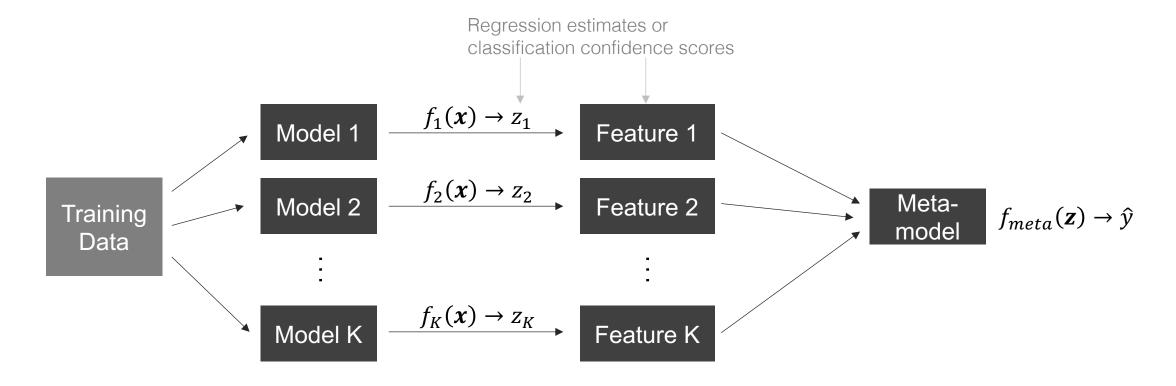

Often this is just a small number of splits (a stump)

Repeat B times

Model Stacking

Train multiple supervised learning techniques (could be different models)

THEN Train a supervised learning technique that includes the **outputs** of the other models as **features**

Supervised Learning Techniques

- Linear Regression
- K-Nearest Neighbors
 - Perceptron
 - Logistic Regression
 - Linear Discriminant Analysis
 - Quadratic Discriminant Analysis
 - Naïve Bayes
- Decision Trees and Random Forests
- Ensemble methods (bagging, boosting, stacking)

Can be used with numerous machine learning techniques, often CART

Appropriate for:

Classification

Regression
